Network Capacity Region and Minimum Energy Function for a Delay-Tolerant Mobile Ad Hoc Network

Rahul Urgaonkar and Michael J. Neely

***Abstract*—We investigate two quantities of interest in a delay-tolerant mobile ad hoc network: the network capacity region and the minimum energy function. The network capacity region is defined as the set of all input rates that the network can stably support considering all possible scheduling and routing algorithms. Given any input rate vector in this region, the minimum energy function establishes the minimum time average power required to support it. In this work, we consider a cell-partitioned model of a delay-tolerant mobile ad hoc network with general Markovian mobility. This simple model incorporates the essential features of locality of wireless transmissions as well as node mobility and enables us to *exactly* compute the corresponding network capacity and minimum energy function. Further, we propose simple schemes that offer performance guarantees that are arbitrarily close to these bounds at the cost of an increased delay.**

***Index Terms*—delay tolerant networks, mobile ad hoc network, capacity region, minimum energy scheduling, queueing analysis**

I. INTRODUCTION

Two quantities that characterize the performance limits of a mobile ad hoc network are the network capacity region and the minimum energy function. The network capacity region is defined as the set of all input rates that the network can stably support considering all possible scheduling and routing algorithms that conform to the given network structure. The minimum energy function is defined as the minimum time average power (summed over all users) required to stably support a given input rate vector in this region. Here, by stability we mean that the input rates are such that for all users, the queues do not grow to infinity and average delays are bounded. In this paper, we exactly compute these quantities for a specific model of a delay-tolerant mobile ad hoc network.

Asymptotic bounds on the capacity of static wireless networks and mobile networks are developed by [2], [3]. The work in [3] shows that for networks with full uniform mobility, if delay constraints are relaxed, a simple 2-hop relay algorithm can support throughput that does not vanish as the number of network nodes N grows large. Recent work in [4] generalizes this model and investigates capacity scaling with non-uniform node mobility and heterogeneous nodes. Capacity-delay tradeoffs in mobile ad hoc networks are considered in [8]–[12]. Flow-based characterization of the network capacity region is presented in several works (e.g., [7], [13], [14]).

However, little work has been done in computing the *exact* capacity and energy expressions for these networks. Exceptions include a closed form expression for the capacity of a fixed grid network in [5], an expression for the exact information theoretic capacity for a single source multicast setting in a wireless erasure network [6], and an expression for the capacity of a mobile ad hoc network in [8] that uses a cell-partitioned structure. The work in [8] quantizes the network geography into a finite number of cells over which users move, and assumes that a single packet can be transmitted between users who are currently in the same cell, while no transmission is possible between users currently in different cells.[1]

In this work, we extend this model to more general scenarios allowing adjacent cell communication and different rate-power combinations. Specifically, we extend the simplified cell-partitioned model of [8] (which only allows same cell communication and considers i.i.d. mobility) to treat adjacent cell communication. We establish exact capacity expressions for general Markovian user mobility processes (possibly non-uniform), assuming only a well-defined steady-state location distribution for the users. Our analysis shows that, similar to [8], the capacity is only a function of the steady-state location distribution of the nodes and a 2-hop relay algorithm is throughput optimal for this extended model as well. Further, our analysis illuminates the optimal decision strategies and precisely defines the throughput optimal control law for choosing between same cell and adjacent cell communication. We then use this insight to design a simple 2-hop relay algorithm that can stabilize the network for all input rates within the network capacity region. We also compute an upper bound on the average delay under this algorithm. (Sec. III)

We next compute the exact expression for the minimum energy required to stabilize this network, for all input rates within capacity. Our result demonstrates a piecewise linear structure for the minimum energy function that corresponds to opportunistically using up successive transmission modes. Then we present a greedy algorithm whose average energy can be pushed arbitrarily close to the minimum energy at the cost of an increased delay. (Sec. IV)

[1] Here a cell represents only a sub-region of the network. There are no base stations in the cells (i.e., this should not be confused with “cellular networks” that use base stations.)

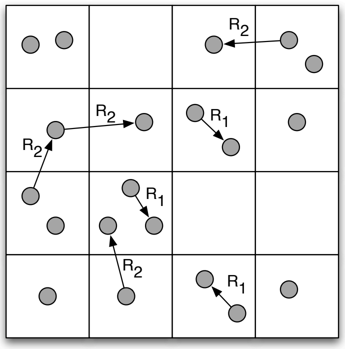

Fig. 1. An illustration of the cell-partitioned network with same and adjacent cell communication. Cells that share an edge are assumed to be adjacent.

Before proceeding further, we emphasize that the network capacity and minimum energy function derived in this paper are subject to the scheduling and routing constraints of our model as described in the next section. Specifically, in this work, we do not consider techniques that "mix" packets, such as network coding or cooperative communication, which can increase the network capacity and reduce energy costs. In fact, in Sec. V, we present an example scenario that shows how network coding in conjunction with the wireless broadcast advantage can increase the capacity for this model. Calculating the network capacity region and the minimum energy function when these strategies are allowed is an open problem in general in network information theory and is beyond the scope of this paper.

II. NETWORK MODEL

A. Cell-Partitioned Structure

We use a cell-partitioned network model (Fig. 1) having C non-overlapping cells (not necessarily of the same size/shape). There are N users roaming from cell to cell over the network according to a mobility process. Each cell $c \in \{1, 2, \dots, C\}$ has a set of adjacent cells $\mathcal{B}_c$ that a user can move into from cell c. The maximum number of adjacent cells of any cell is bounded by a finite constant J. We define the network user density as $\theta = N/C$ users/cell. For simplicity, N is assumed to be even and $N \geq 2$. Note that there could be "gaps" in the cell structure due to infeasible geographic locations. We assume that the gaps do not partition the network, so that it is possible for a single user to visit all cells. We assume C is the number of valid cells, not including such gaps.

B. Mobility Model

Time is slotted so that each user remains in its current cell for a timeslot and potentially moves to an adjacent cell at the end of the slot. We assume that each user i moves independently of the other users according to a mobility process that is described by a finite state ergodic Markov Chain. In particular, let $\mathbf{P} = \{P_{ij}\}_{C\times C}$ be the transition probability matrix of this Markov Chain. Then P_{ij} represents the conditional probability that a user moves to cell j in the current slot given that it was in cell i in the last slot. Note that $P_{ij} > 0$ only if j is an adjacent cell of i, i.e., $j \in \mathcal{B}_i$. It can be shown that the resulting mobility process has a well-defined steady-state location distribution $\boldsymbol{\pi} = \{\pi_c\}_{1\times C}$ over the cells $c \in \{1, 2, \dots, C\}$ that satisfies $\boldsymbol{\pi}\mathbf{P} = \boldsymbol{\pi}$ and is the same for all users. However, this distribution could be non-uniform over the cells. We assume that in each slot, users are aware of the set of other users in the same cell and in adjacent cells. However, the transition probabilities associated with the Markov Chain $\mathbf{P}$ are not necessarily known.

It can be shown (see, for example, [18]) that the mobility process discussed above has the following property. Let $\chi(t) \in \{1, \dots, C\}$ denote the location of a user in timeslot t. Then, for all integers $d > 0$, there exist positive constants α, γ such that $\forall c \in \{1, 2, \dots, C\}$, the following holds:

$$\pi_c(1-\alpha\gamma^d) \leq Pr[\chi(t+d) = c|\chi(t)] \leq \pi_c(1+\alpha\gamma^d) \quad (1)$$

where $\alpha > 1$ and $0 < \gamma < 1$. Moreover, the decay factor γ is given by the second largest eigenvalue of the transition probability matrix $\mathbf{P}$ (see [17]). From this, it can be seen that for any $\epsilon > 0$, choosing $d = \lceil \frac{\log(\epsilon/\alpha)}{\log(\gamma)} \rceil$ ensures that the conditional probability that the user is in cell c at time $t+d$ is within $\pi_c\epsilon$ of the steady-state probability π_c of being in cell c, irrespective of the current location. This implies that the Markov Chain converges to its steady-state probability distribution exponentially fast. Using the independence of user mobility processes, the following can be shown about functionals of the joint user location process $\vec{\chi}(t)$:

Lemma 1: Let $\vec{\chi}(t) = (\chi_1(t), \dots, \chi_N(t))$ be the vector of current user locations, where $\chi_i(t)$ represents the cell of user i in slot t. Let $f(\vec{\chi}(t))$ be any non-negative function of $\vec{\chi}(t)$, i.e., $f(\vec{\chi}(t)) \geq 0 \ \forall \ \vec{\chi}(t)$. Define f_{av} as the expectation of $f(\vec{\chi}(t))$ over the steady-state distribution of $\vec{\chi}(t)$:

$$f_{av} \triangleq \sum_{c_1, c_2, \dots, c_N} f(c_1, \dots, c_N) \prod_{i=1}^{N} \pi_{c_i}$$

Then for all d such that $\alpha\gamma^d \leq \frac{1}{N^2}$, we have

$$f_{av}(1-2N\alpha\gamma^d) \leq \mathbb{E}\left\{f(\vec{\chi}(t+d))|\vec{\chi}(t)\right\} \leq f_{av}(1+2N\alpha\gamma^d)$$

Proof: See Appendix A. ■

C. Traffic Model

We assume that there are N unicast sessions in the network with each node being the source of one session and the destination of another session. Packets are assumed to arrive at the source of each session i according to an i.i.d. arrival process $A_i(t)$ of rate λ_i. We assume that in any slot, the maximum number of arrivals to any session i is bounded, i.e., $A_i(t) \leq A_{max}$. While our analysis holds for the general source-destination pairing, for simplicity, we assume that N is even with the following one-to-one pairing between users: $1 \leftrightarrow 2, 3 \leftrightarrow 4, \dots, (N-1) \leftrightarrow N$, i.e., packets generated by user 1 are destined for user 2 and those generated by user 2 are destined for user 1 and so on. This assumption simplifies the computation of the capacity in closed form in Theorem 1 and will be used for the rest of the paper.

D. Communication Model

We assume that two users can communicate only if they are in the same cell or in adjacent cells. Further, if the communication takes place in the same cell, R_1 packets can be transmitted from the sender to the receiver if the sender uses full power. If the receiver is in an adjacent cell, R_2 packets can be transmitted with full power. We assume that R_1 and R_2 are non-negative integers and that $R_1 \geq R_2$. Power allocation is restricted to the set $\{0, 1\}$, i.e., each user either uses zero power or full power. For simplicity, we assume that the communication cost consists only of the transmission power. The analysis presented can be easily extended to the case with non-zero reception power by defining the communication cost as the total power (including transmission and reception) required for sending $R_1(R_2)$ packets from a transmitter to a receiver in the same (adjacent) cell.

We allow *at most* one transmitter in a cell at any given time slot, though the cell may have multiple receivers (due to possible adjacent cell communication). Further, a user may potentially transmit and receive simultaneously. This model is conceivable if the users in neighboring cells use orthogonal communication channels. This model allows us to treat scheduling decisions in each cell *independently* of all other cells, thereby enabling us to derive closed form expressions for capacity and minimum energy.

E. Discussion of Model

While an idealization, the cell-partitioned model captures the essential features of locality of wireless transmissions as well as node mobility and allows us to compute exact expressions for the network capacity and minimum energy function. This model is reasonable when nodes use non-interfering orthogonal channels in adjacent cells. We also refer to Section I-A of [8] for further discussion on the cell-partitioned network assumption.

In this work, we restrict our attention to network control algorithms that operate according to the network structure described above. A general algorithm within this class will make scheduling decisions about what packet to transmit, when, and to whom. For example, it may decide to transmit to a user in an adjacent cell rather than to some user in the same cell, even though the transmission rate is smaller. However, we assume that the packets themselves are kept intact and are not "mixed" (for example, using cooperative communication and/or network coding). Allowing such strategies can increase the capacity, although computing the exact capacity region remains a challenging open problem in general. In Sec. V, we present an example that shows how network coding in conjunction with the wireless broadcast advantage can increase the capacity for this model. However, we note that if we remove the broadcast feature, then the scenario considered in this paper becomes a network coding problem for multiple unicasts over an undirected graph, for which it is not yet known if network coding provides any gains over plain routing (see further discussion in [16]).

III. NETWORK CAPACITY

In this section, we compute the exact capacity of the network model described in the previous section. For simplicity, we assume that all users receive packets at the same rate (i.e., $\lambda_i = \lambda$ for all i). The capacity of the network is then described by a scalar quantity which denotes the maximum rate λ that the network can stably support. Recall that network user density $\theta = N/C$ users/cell. Then we have the following:

Theorem 1: The capacity of the network (in packets/slot) is given by:

$$\mu = \begin{cases} \frac{R_1 q + R_1 p + R_2 q' + R_2 p'}{2\theta} & \text{if } R_1 \geq 2R_2 \\ \frac{2R_1 q + 2R_2 q'' + R_1 p'' + R_2 (p' - q')}{2\theta} & \text{if } 2R_2 > R_1 \geq R_2 \end{cases}$$

where
$q = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding a source-destination pair in cell c in a timeslot]
$p = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding at least 2 users in cell c in a timeslot]
$q' = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding exactly 1 user in cell c and its destination in an adjacent cell in a timeslot]
$p' = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding exactly 1 user in cell c and at least 1 user in an adjacent cell in a timeslot]
$q'' = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding no source-destination pair in cell c but at least 1 source-destination pair with an adjacent cell in a timeslot]
$p'' = \frac{1}{C}\sum_{c=1}^{C} Pr$[finding no source-destination pair in cell c and any adjacent cell but at least 2 users in the cell c in a timeslot]

The probabilities in the summations above are the probabilities associated with the steady-state cell location distributions of the users. Using the independence of user mobility processes and the same steady-state cell location distribution $\boldsymbol{\pi} = \{\pi_c\}_{1\times C}$ for all users, we can exactly compute these probabilities for our model. These are given by (see Appendix B for detailed derivation):

$$q = \frac{1}{C}\sum_{c=1}^{C}\Big(1 - (1 - \pi_c^2)^{\frac{N}{2}}\Big)$$

$$p = \frac{1}{C}\sum_{c=1}^{C}\Big(1 - (1 - \pi_c)^N - N\pi_c(1 - \pi_c)^{N-1}\Big)$$

$$q' = \frac{1}{C}\sum_{c=1}^{C}\Big(\Pi_{adj}(c) N\pi_c(1 - \pi_c)^{N-1}\Big)$$

$$p' = \frac{1}{C}\sum_{c=1}^{C}\Big(1 - (1 - \Pi_{adj}(c))^{N-1}\Big) N\pi_c(1 - \pi_c)^{N-1}$$

$$q'' = \frac{1}{C}\sum_{c=1}^{C}\sum_{i=1}^{\frac{N}{2}} 2^i \binom{\frac{N}{2}}{i} \pi_c^i (1 - \pi_c)^{N-i}\Big(1 - (1 - \Pi_{adj}(c))^i\Big)$$

$$p'' = \frac{1}{C}\sum_{c=1}^{C}\sum_{i=2}^{\frac{N}{2}} 2^i \binom{\frac{N}{2}}{i} \pi_c^i (1 - \pi_c)^{N-i}(1 - \Pi_{adj}(c))^i \qquad (2)$$

Here, $\Pi_{adj}(c)$ denotes the sum of the conditional steady-state probability of a user being in any adjacent cell of cell c given that this user is not in cell c, i.e., $\Pi_{adj}(c) = \frac{1}{1-\pi_c}\sum_{i\in\mathcal{B}_c}\pi_i$. Thus, the network can stably support users simultaneously communicating at any rate $\lambda < \mu$. We prove the theorem in two parts. First, we establish the necessary condition by deriving an upper bound on the capacity of *any* stabilizing algorithm. Then, we establish sufficiency by presenting a specific scheduling strategy and showing that the average delay is bounded under that strategy.

A. Proof of Necessity

Proof: Let Ψ be the set of all stabilizing scheduling policies. Consider any particular policy $\psi \in \Psi$. Suppose it successfully delivers $X^{\psi}_{ab}(T)$ packets from sources to destinations involving "a" same cell transmissions and "b" adjacent cell transmissions in the interval $(0, T)$. Fix $\epsilon > 0$. For stability, there must exist arbitrarily large values of T such that the total output rate is within ϵ of total input rate. Thus:

$$\frac{\sum_{a=0}^{\infty}\sum_{b=0}^{\infty} X^{\psi}_{ab}(T)}{T} \geq N\lambda - \epsilon \tag{3}$$

Define $Y^{\psi}(T)$ as the total number of packet transmissions in $(0, T)$ under policy ψ. Then, $Y^{\psi}(T)$ is *at least* $\sum_{a=0}^{\infty}\sum_{b=0}^{\infty}(a+b)X^{\psi}_{ab}(T)$ (because these many packets were certainly delivered). Thus, we have

$$\begin{aligned}\frac{1}{T}Y^{\psi}(T) &\geq \frac{1}{T}\sum_{a=0}^{\infty}\sum_{b=0}^{\infty}(a+b)X^{\psi}_{ab}(T)\\ &\geq \frac{1}{T}\sum_{a+b<2} X^{\psi}_{ab}(T) + \frac{2}{T}\sum_{a+b\geq 2} X^{\psi}_{ab}(T)\\ &\geq \frac{1}{T}\sum_{a+b<2} X^{\psi}_{ab}(T) + 2(N\lambda - \epsilon) - \frac{2}{T}\sum_{a+b<2} X^{\psi}_{ab}(T)\end{aligned}$$

where the last inequality is obtained using (3). Hence, noting that ϵ can be chosen to be arbitrarily small, we have:

$$\lambda \leq \lim_{T\to\infty} \frac{Y^{\psi}(T) + X^{\psi}_{10}(T) + X^{\psi}_{01}(T)}{2TN} \tag{4}$$

Define $Y^{\psi}_{c}(\tau)$ as the total number of packet transmissions in cell c at timeslot τ under policy ψ. Also define $X^{\psi}_{10,c}(\tau)$ and $X^{\psi}_{01,c}(\tau)$ as the number of packets delivered by same cell direct and adjacent cell direct transmission respectively in cell c at timeslot τ. Then $Y^{\psi}(T) + X^{\psi}_{10}(T) + X^{\psi}_{01}(T)$ can be written as a sum over all timeslots $\tau \in (0, T)$ and all cells c as follows:

$$\begin{aligned}&Y^{\psi}(T) + X^{\psi}_{10}(T) + X^{\psi}_{01}(T)\\ &= \sum_{\tau=0}^{T-1}\sum_{c=1}^{C}\Big(Y^{\psi}_{c}(\tau) + X^{\psi}_{10,c}(\tau) + X^{\psi}_{01,c}(\tau)\Big)\\ &\leq \sum_{\tau=0}^{T-1}\sum_{c=1}^{C}\max_{\omega\in\Psi}\Big(\hat{Y}^{\omega}_{c}(\tau) + \hat{X}^{\omega}_{10,c}(\tau) + \hat{X}^{\omega}_{01,c}(\tau)\Big)\end{aligned} \tag{5}$$

where $\hat{Y}^{\omega}_{c}(\tau)$ denotes the total number of packet transmission *opportunities* in cell c at timeslot τ under any policy ω. Similarly, $\hat{X}^{\omega}_{10,c}(\tau)$ and $\hat{X}^{\omega}_{01,c}(\tau)$ denote the total number of packet transmission *opportunities* that use same cell direct and adjacent cell direct transmissions respectively in cell c at timeslot τ. Note that these do not depend on the queue backlogs and therefore can be different from the actual number of packet transmissions (for example, when enough packets are not available).

Let $\hat{Z}^{\omega}_{c}(\tau) = \hat{Y}^{\omega}_{c}(\tau) + \hat{X}^{\omega}_{10,c}(\tau) + \hat{X}^{\omega}_{01,c}(\tau)$. Also define the following indicator decision variables for any policy ω for some $\tau \in (0, T)$ and $c \in \{1, 2, \ldots, C\}$:

$$I^{1}_{c}(\tau) = \begin{cases} 1 & \text{if a same cell direct transmission can} \\ & \text{be scheduled in cell } c \text{ in slot } \tau \\ 0 & \text{else} \end{cases}$$

$$I^{2}_{c}(\tau) = \begin{cases} 1 & \text{if a same cell relay transmission can} \\ & \text{be scheduled in cell } c \text{ in slot } \tau \\ 0 & \text{else} \end{cases}$$

$$I^{3}_{c}(\tau) = \begin{cases} 1 & \text{if an adjacent cell direct transmission can} \\ & \text{be scheduled in cell } c \text{ in slot } \tau \\ 0 & \text{else} \end{cases}$$

$$I^{4}_{c}(\tau) = \begin{cases} 1 & \text{if an adjacent cell relay transmission can} \\ & \text{be scheduled in cell } c \text{ in slot } \tau \\ 0 & \text{else} \end{cases}$$

Note that the transmission rates associated with these decision variables are R_1, R_1, R_2 and R_2 respectively. Then, we can express $\hat{Z}^{\omega}_{c}(\tau)$ as follows:

$$\begin{aligned}&\hat{Z}^{\omega}_{c}(\tau) = \hat{Y}^{\omega}_{c}(\tau) + \hat{X}^{\omega}_{10,c}(\tau) + \hat{X}^{\omega}_{01,c}(\tau) = R_1 I^{1}_{c}(\tau) + R_1 I^{2}_{c}(\tau)\\ &+ R_2 I^{3}_{c}(\tau) + R_2 I^{4}_{c}(\tau) + \hat{X}^{\omega}_{10,c}(\tau) + \hat{X}^{\omega}_{01,c}(\tau)\\ &= R_1 I^{1}_{c}(\tau) + R_1 I^{2}_{c}(\tau) + R_2 I^{3}_{c}(\tau) + R_2 I^{4}_{c}(\tau) + R_1 I^{1}_{c}(\tau)\\ &+ R_2 I^{3}_{c}(\tau) = 2R_1 I^{1}_{c}(\tau) + R_1 I^{2}_{c}(\tau) + 2R_2 I^{3}_{c}(\tau) + R_2 I^{4}_{c}(\tau)\end{aligned}$$

Note that under any scheduling policy, only one of the decision variables can be 1 and the rest are 0. Thus, the preference order for decisions to maximize $\hat{Z}^{\omega}_{c}(\tau)$ is evident. Specifically, it would be $I^{1}_{c}(\tau) \succ I^{2}_{c}(\tau) \succ I^{3}_{c}(\tau) \succ I^{4}_{c}(\tau)$ when $R_1 \geq 2R_2$ and $I^{1}_{c}(\tau) \succ I^{3}_{c}(\tau) \succ I^{2}_{c}(\tau) \succ I^{4}_{c}(\tau)$ when $R_2 \leq R_1 < 2R_2$. Thus, in each cell c, $\hat{Z}^{\omega}_{c}(\tau)$ is maximized by the policy ω that chooses the scheduling decisions in this preference order, choosing a less preferred decision only when none of the more preferred decisions are possible in that cell.

Define $Z_c(\tau) = \max_{\omega\in\Psi} \hat{Z}^{\omega}_{c}(\tau)$. Then using (4) and (5), we have

$$\lambda \leq \lim_{T\to\infty} \frac{1}{2TN}\sum_{\tau=0}^{T-1}\sum_{c=1}^{C} Z_c(\tau)$$

As $Z_c(\tau)$ can take only a finite number of values (namely $R_1, R_2, 2R_1, 2R_2$ and 0) and is a function of the current state of the ergodic user location processes, the time average of $Z_c(\tau)$ is exactly equal to its expectation with respect to the steady-state user location distribution. Thus, the bound above can be computed by calculating the expectation of $Z_c(\tau)$ using the steady-state probabilities associated with the indicator variables and summing over all cells. When $R_1 \geq 2R_2$, this is given by:

$$\begin{aligned}
&\lim_{T\to\infty} \frac{1}{2TN} \sum_{\tau=0}^{T-1} \sum_{c=1}^{C} Z_c(\tau) \\
&= \frac{1}{2N} \sum_{c=1}^{C} \mathbb{E}\left\{Z_c(\tau)\right\} \\
&= \frac{2R_1 q + R_1(p-q) + 2R_2 q' + R_2(p'-q')}{2\theta}
\end{aligned}$$

and when $R_2 \leq R_1 < 2R_2$, this is given by:

$$\begin{aligned}
&\lim_{T\to\infty} \frac{1}{2TN} \sum_{\tau=0}^{T-1} \sum_{c=1}^{C} Z_c(\tau) \\
&= \frac{1}{2N} \sum_{c=1}^{C} \mathbb{E}\left\{Z_c(\tau)\right\} \\
&= \frac{2R_1 q + 2R_2 q'' + R_1 p'' + R_2(p'-q')}{2\theta}
\end{aligned}$$

This establishes the necessary condition for the network capacity. ■

Note that the above preference order clearly spells out the structure of the throughput optimal strategy. Specifically, depending on the values of R_1 and R_2, this order can be used to decide between same cell relay and adjacent cell direct transmission. We use this insight to design a throughput-optimal 2-hop relay algorithm in the next section. Also note the factor of 2 with the decision variables corresponding to direct source-destination transmission. Intuitively, each such transmission opportunity is better than a similar opportunity between source-relay or relay-destination by a factor of 2 since the indirect transmissions need twice as many opportunities to deliver a given number of packets to the destination as compared to direct transmissions.

B. Proof of Sufficiency

Now we present an algorithm that makes stationary, randomized scheduling decisions independent of the queue backlogs and show that it gives bounded delay for any rate $\lambda < \mu$, i.e., there exists a ρ such that $0 \leq \rho < 1$ and $\lambda = \rho\mu$. We only consider the case when $R_1 \geq 2R_2$. The other case is similar and is not discussed.

2-Hop Relay Algorithm: Every timeslot, for all cells, do the following:

1) If there exists a source-destination pair in the cell, randomly choose such a pair (uniformly over all such pairs in the cell). If the source has new packets for the destination, transmit at rate R_1. Else remain idle.
2) If there is no source-destination pair in the cell but there are at least 2 users in the cell, randomly designate one user as the sender and another as the receiver. Then, with probability $\frac{1-\delta}{2}$ (where $0 < \delta < 1$ and $\delta = \delta(\rho)$ to be determined later), perform the first action below. Else, perform the second.
    a) *Send new Relay packets in same cell*: If the transmitter has new packets for its destination, transmit at rate R_1. Else remain idle.
    b) *Send Relay packets to their Destination in same cell*: If the transmitter has packets for the receiver, transmit at rate R_1. Else remain idle.
3) If there is only 1 user in the cell and its destination is present in one of the adjacent cells, transmit at rate R_2 if new packets present. Else remain idle.
4) If there is only 1 user in the cell and its destination is not present in one of the adjacent cells but there is at least one user in an adjacent cell, randomly designate one such user as the receiver and the only user in the cell as the transmitter. Then, with probability $\frac{1-\delta}{2}$ (where $0 < \delta < 1$ and $\delta = \delta(\rho)$ to be determined later), perform the first action below. Else, perform the second.
    a) *Send new Relay packets in adjacent cell*: If the transmitter has new packets for its destination, transmit at rate R_2. Else remain idle.
    b) *Send Relay packets to their Destination in adjacent cell*: If the transmitter has packets for the receiver, transmit at rate R_2. Else remain idle.

This algorithm is motivated by the proof of necessity of Theorem 1 since it follows the same preference order in making scheduling decisions. Note that this algorithm restricts the path lengths of all packets to *at most* 2 hops because any packet that has been transmitted to a relay node is restricted from being transmitted to any other node except its destination.

To analyze the performance of this algorithm, we make use of a Lyapunov drift analysis [7]. Consider a network of N queues operating in slotted time, and let $\vec{U}(t) = (U_1(t), U_2(t), \ldots, U_N(t))$ represent the vector of backlogged packets in each of the queues at timeslot t. Let $L(\vec{U}(t))$ be a non-negative function of the unfinished work $\vec{U}(t)$, called a Lyapunov function. Define the conditional Lyapunov drift $\Delta(t,d)$ at time $t > d$ (where $d \geq 0$ in a fixed integer) as follows:

$$\Delta(t,d) \triangleq \mathbb{E}\left\{L(\vec{U}(t+1)) - L(\vec{U}(t)) | \vec{U}(t-d)\right\}$$

Then we have the following lemma.

Lemma 2: Lyapunov Drift Lemma: If there exists a positive integer d such that for all timeslots $t > d$ and for all $\vec{U}(t)$, the conditional Lyapunov drift $\Delta(t,d)$ satisfies:

$$\Delta(t,d) \leq B - \epsilon \sum_{i=1}^{N} U_i(t-d) \tag{6}$$

for some positive constants B and ϵ, and if $\mathbb{E}\left\{L(\vec{U}(d))\right\} < \infty$, then the network is stable, and we have the following bound on the time average total queue backlog:

$$\limsup_{t\to\infty} \frac{1}{t} \sum_{\tau=0}^{t-1} \sum_{i=1}^{N} \mathbb{E}\left\{U_i(\tau)\right\} \leq \frac{B}{\epsilon} \tag{7}$$

Proof: This can be shown using a telescoping sum technique (similar to related proof in [7]) and is omitted for brevity. ■

We now make use of this lemma to analyze the performance of the 2-Hop Relay Algorithm.

Theorem 2: For the cell partitioned network (with N nodes and C cells) as described in Sec. II, with capacity $\mu = \frac{R_1p+R_2p'+R_1q+R_2q'}{2\theta}$ and input rate λ for each user such that $\lambda = \rho\mu$ for some $0 \leq \rho < 1$, and user mobility model as described in Sec. II-B, the average packet delay $\overline{D}$ under the 2-Hop Relay Algorithm with $\delta = \frac{1-\rho}{4}$ satisfies:

$$\overline{D} \leq \frac{BN(2d+1)}{\lambda\mu\kappa(1-\rho)} \tag{8}$$

where B is a constant given by (11), κ is a positive constant given by $\kappa = \frac{R_1p+R_2p'-R_1q-R_2q'}{R_1p+R_2p'+R_1q+R_2q'}$, and d is a finite integer that is related to the mixing time of the joint user mobility process and is given by $d = \left\lceil \frac{\log(\frac{8N^2\alpha}{1-\rho})}{\log(1/\gamma)} \right\rceil$.

Proof: Let $U_i^{(c)}(t)$ represent the total backlog of type c (i.e., number of packets destined for node c) that are queued up in node i at time t. The queueing dynamics of $U_i^{(c)}(t)$ satisfies the following for all $c \neq i$:

$$\begin{aligned} U_i^{(c)}(t+1) \leq \max\Big[U_i^{(c)}(t) - \sum_b \mu_{ib}^{(c)}(t), 0\Big] + \sum_a \mu_{ai}^{(c)}(t) \\ + A_i^{(c)}(t) \end{aligned} \tag{9}$$

where $A_i^{(c)}(t)$ =number of new type c arrivals to source node i at the beginning of timeslot t and $\mu_{ab}^{(c)}(t)$ =rate offered to type c packets in timeslot t with node a as transmitter and node b as receiver. The above is an inequality because the actual number of packets transmitted from the other nodes to node i (for relaying) could be less than the incoming transmission rate $\sum_a \mu_{ai}^{(c)}(t)$ when these nodes do not have enough packets. Now define a Lyapunov function $L(\vec{U}(t)) = \sum_{i=1}^N \sum_{c\neq i} (U_i^{(c)}(t))^2$. Using (9), the conditional Lyapunov drift $\Delta(t,d)$ can be expressed as follows:

$$\begin{aligned} \Delta(t,d) \leq BN - 2\sum_{i=1}^N \sum_{c\neq i} \mathbb{E}\Bigg\{ U_i^{(c)}(t) \times \\ \Big(\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)\Big) | \vec{U}(t-d) \Bigg\} \end{aligned} \tag{10}$$

Here, B is given by:

$$B = (A_{max} + \mu_{max}^{in})^2 + (\mu_{max}^{out})^2 \tag{11}$$

where μ_{max}^{in} = maximum transmission rate into any node = $R_1 + JR_2$, where J is the maximum number of adjacent cells of any cell (Sec. II-A) and μ_{max}^{out} = maximum transmission rate out of any node = R_1.

We now use the following sample path relations to express (10) in terms of the queue backlog values at time $(t-d)$. Specifically, we have the following for all $t > d$ where d is a positive integer (to be determined later) for all $i \neq c$.

$$\sum_{c\neq i} U_i^{(c)}(t-d) + d(A_{max} + \mu_{max}^{in}) \geq \sum_{c\neq i} U_i^{(c)}(t)$$

$$\sum_{c\neq i} U_i^{(c)}(t-d) - d\mu_{max}^{out} \leq \sum_{c\neq i} U_i^{(c)}(t)$$

These follow by noting that the queue backlog at time t cannot be smaller than the queue backlog at time $(t-d)$ minus the maximum possible departures in duration $(t-d, d)$. Similarly, it cannot be larger than the queue backlog at time $(t-d)$ plus the maximum possible arrivals in duration $(t-d, d)$. Using these, we can express (10) in terms of the "delayed" queue backlogs $U_i^{(c)}(t-d)$ as follows:

$$\begin{aligned} \Delta(t,d) \leq BN(2d+1) - 2\sum_{i=1}^N \sum_{c\neq i} U_i^{(c)}(t-d) \times \\ \mathbb{E}\Bigg\{ \sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t) | \vec{U}(t-d) \Bigg\} \end{aligned} \tag{12}$$

Let $\mathcal{T}(t-d) = (\vec{\chi}(t-d), \vec{U}(t-d))$ represent the composite system state at time $(t-d)$ given by the user locations and queue backlogs. Since the 2-Hop Relay Algorithm makes control decisions only as a function of the current user locations, the resulting service rates are functionals of the Markovian mobility processes. By the Markovian property of the $\vec{\chi}(t-d)$ process, any functionals of this also converge exponentially fast to their steady-state values. Thus, using Lemma 1, when $\alpha\gamma^d \leq 1/N^2$, we have the following bounds:

$$\mathbb{E}\Bigg\{ \sum_b \mu_{ib}^{(c)}(t) | \vec{U}(t-d) \Bigg\} \geq \Big(\sum_b \overline{\mu}_{ib}^{(c)}\Big)(1 - 2N\alpha\gamma^d) \tag{13}$$

$$\mathbb{E}\Bigg\{ \sum_a \mu_{ai}^{(c)}(t) | \vec{U}(t-d) \Bigg\} \leq \Big(\sum_a \overline{\mu}_{ai}^{(c)}\Big)(1 + 2N\alpha\gamma^d) \tag{14}$$

where $\overline{\mu}_{ib}^{(c)}, \overline{\mu}_{ai}^{(c)}$ are the steady-state service rates achieved by the 2-Hop Relay Algorithm. We now compute these values and use the inequalities (13), (14) to obtain a bound on (12). We have the following 2 cases:

1) *Node i Generates Type c Packets:* In this case, $\mathbb{E}\Big\{A_i^{(c)}(t)\Big\} = \lambda$ and $\sum_a \mu_{ai}^{(c)}(t) = 0$ (since under the 2-Hop Relay Algorithm, a source node would never get back a packet that it generates). To calculate $\sum_b \overline{\mu}_{ib}^{(c)}$, we note that the outgoing service rate for packets generated by the source is equal to the sum of the rate at which the source is scheduled to transmit directly to its destination and the rate at which it is scheduled to transmit type c packets to any of the relay nodes. Let these rates be r_1 and r_2 respectively. Also let the transmission rate at which it is scheduled to transmit relay packets to their destinations be r_3. Since the 2-Hop Relay Algorithm only schedules transmissions of these types, the total rate of transmissions over the network is given by $N(r_1 + r_2 + r_3)$. Using the probability of choosing source-relay and relay-destination transmissions, we have: $r_2 = \frac{1-\delta}{1+\delta} r_3$. In the 2-Hop Relay Algorithm, a direct source-to-destination transmission is scheduled whenever there is a source-destination pair in the same cell or there is only 1 node in a cell and its destination is in an adjacent cell (and independent of the actual queue backlog values). Thus, using the definitions of q and q' from the statement of Theorem 1, we have: $Nr_1 = C(R_1q + R_2q')$. Similarly, the sum total transmissions in the network can be expressed in terms of the quantities p and p' as follows: $N(r_1 + r_2 + r_3) = C(R_1p + R_2p')$. Using these to solve for r_1, r_2, r_3 and simplifying, we have

$$r_1 = \mu(1-\kappa), \quad r_2 = \mu\kappa(1-\delta), \quad r_3 = \mu\kappa(1+\delta) \tag{15}$$

where $\kappa \triangleq \frac{R_1 p + R_2 p' - R_1 q - R_2 q'}{R_1 p + R_2 p' + R_1 q + R_2 q'}$. Note that $0 < \kappa < 1$ (since $p > q$ and $p' > q'$). Therefore, we have:

$$\sum_b \overline{\mu}_{ib}^{(c)} = r_1 + r_2 = \mu - \mu\kappa\delta$$

Let $\delta = \frac{1-\rho}{4}$ and $\alpha\gamma^d = \frac{\delta}{2N^2} = \frac{1-\rho}{8N^2}$. Note that this choice of δ represents a valid probability since $0 \leq \rho < 1$. Then, using (13), the last term of (12) under this case can be expressed as:

$$\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\} \geq$$

$$\Big(\sum_b \overline{\mu}_{ib}^{(c)}\Big)(1 - 2N\alpha\gamma^d) - \lambda = (\mu - \mu\kappa\delta)(1 - \frac{\delta}{N}) - \rho\mu$$

$$\geq \mu\Big[(1-\delta)^2 - \rho\Big] \geq \mu(1 - 2\delta - \rho) = \frac{\mu(1-\rho)}{2}$$

where we used the fact that $(1 - \kappa\delta)(1 - \frac{\delta}{N}) \geq (1-\delta)^2$.

2) *Node i Relays Type c Packets:* Note that $N > 2$ for this case to happen. From our traffic model, we know that in this case $A_i^{(c)}(t) = 0$ for all t. Further, under the 2-Hop Relay Algorithm, $\mu_{ai}^{(c)}(t) > 0$ only if node a is the source for type c packets. Also $\mu_{ib}^{(c)}(t) > 0$ only if $b = c$. To compute $\sum_b \overline{\mu}_{ib}^{(c)}$ and $\sum_a \overline{\mu}_{ai}^{(c)}$ for this case, note that the 2-Hop Relay Algorithm schedules relay transmissions such that all $(N-2)$ relay packet types are equally likely. Thus we have:

$$\sum_b \overline{\mu}_{ib}^{(c)} = \frac{r_3}{N-2}, \ \sum_a \overline{\mu}_{ai}^{(c)} = \frac{r_2}{N-2}$$

Let $\delta = \frac{1-\rho}{4}$ and $\alpha\gamma^d = \frac{\delta}{2N^2} = \frac{1-\rho}{8N^2}$. Then, using (13), (14), the last term of (12) under this case can be expressed as:

$$\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\}$$

$$\geq \Big(\sum_b \overline{\mu}_{ib}^{(c)}\Big)(1 - 2N\alpha\gamma^d) - \Big(\sum_a \overline{\mu}_{ai}^{(c)}\Big)(1 + 2N\alpha\gamma^d)$$

$$= \Big(\sum_b \overline{\mu}_{ib}^{(c)} - \sum_a \overline{\mu}_{ai}^{(c)}\Big) - \Big(\sum_b \overline{\mu}_{ib}^{(c)} + \sum_a \overline{\mu}_{ai}^{(c)}\Big)\frac{\delta}{N}$$

$$= \frac{(r_3 - r_2) - \frac{(r_3 + r_2)\delta}{N}}{N-2} = \frac{2\mu\kappa\delta}{N-2}\Big(1 - \frac{1}{N}\Big) \geq \frac{\mu\kappa(1-\rho)}{2N}$$

where we used (15). Combining these two cases, with $\delta = \frac{1-\rho}{4}$ and $\alpha\gamma^d = \frac{1-\rho}{8N^2}$:

$$\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\} \geq \frac{\mu\kappa(1-\rho)}{2N}$$

Using this in (12), we get:

$$\Delta(t,d) \leq BN(2d+1) - \frac{\mu\kappa(1-\rho)}{N}\sum_{i=1}^{N}\sum_{c \neq i} U_i^{(c)}(t-d)$$

This is in a form that fits (6). Using the Lyapunov Drift Lemma, we get

$$\limsup_{t\to\infty} \frac{1}{t}\sum_{\tau=0}^{t-1}\sum_{i \neq c} \mathbb{E}\left\{U_i^{(c)}(\tau)\right\} \leq \frac{BN^2(2d+1)}{\mu\kappa(1-\rho)} \qquad (16)$$

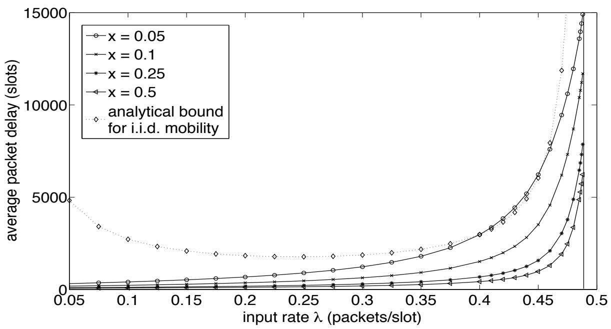

Fig. 2. Average packet delay under the 2-Hop Relay Algorithm in a network of 16 cells with 20 nodes for different mixing times of the mobility process.

The total input rate into the network is $N\lambda$. Thus, using Little's Theorem, the average delay per packet is bounded by $\frac{BN(2d+1)}{\lambda\mu\kappa(1-\rho)}$. ■

C. Discussion and Simulation Example

The proof of the capacity for the cell-partitioned network can be used to consider more general scheduling restrictions. From (5), it amounts to:

$$\lambda \leq \frac{1}{2N}\mathbb{E}\left\{\max_{\omega\in\Psi}\sum_{c=1}^{C}\Big(Y_c^{\omega}(t) + X_{10,c}^{\omega}(t) + X_{01,c}^{\omega}(t)\Big)\right\}$$

If the bound on the right hand side can be achieved by any policy (potentially randomized) that takes decisions only as a function of the current network state, then we can design a deterministic policy that is throughput optimal by scheduling to maximize $\sum_{c=1}^{C}\Big(Y_c^{\omega}(t) + X_{10,c}^{\omega}(t) + X_{01,c}^{\omega}(t)\Big)$ subject to the network restrictions. For the specific cell-partitioned model considered here, this maximization is achieved by following the preference order of the decision variables in each cell separately as described earlier. This enables us to exactly compute the capacity of the network. It is possible to do the same for extensions to this model involving other constraints. For example, under the constraint that a user cannot simultaneously transmit and receive, the above maximization becomes a maximum-weight match problem. Similarly, one could allow more than one transmitter per cell, in which case we would need to define more indicator decision variables for all possible control options.

We next consider an example network consisting of 20 nodes and 16 cells as shown in Fig. 1. The nodes move from one cell to another independently according to a Markovian random walk. Specifically, at the end of every slot, a node stays in its current cell with probability $(1-x)$, else it decides to move randomly one step in either the North, West, South, or East directions with probability x. If there is no feasible adjacent cell, then the user remains in the current cell. It can be shown that the resulting steady-state location distribution is uniform over all cells for all $0 \leq x < 1$. Thus, $\pi_c = \frac{1}{16}$ for all cells c. Next we assume that $R_1 = 2$ and $R_2 = 1$ packets/slot. Then using Theorem 1, the capacity for this network is given by $\mu = \frac{R_1 q + R_1 p + R_2 q' + R_2 p'}{2\theta}$ and can be calculated exactly. Specifically, we get $p = 0.358, q =$

$0.038, p' = 0.357, q' = 0.073$ and the network capacity is given by $\mu = 0.489$ packets/slot.

We next simulate the 2-Hop Relay Algorithm on this network. New packets arrive at each source node according to independent Bernoulli processes, so that a single packet arrives i.i.d. with probability λ every slot. In Fig. 2, we plot the average packet delay vs. λ for different values of x. We also plot the analytical bound (8) of Theorem 2 for the i.i.d. mobility case (for which $d = 0$). It can be seen that the average delay goes to infinity as λ is pushed closer to the capacity $\mu = 0.489$ packets/slot (shown by the vertical line in Fig. 2). While the network capacity is the same for all values of x (since x does not affect the steady-state location distribution), the average delay increases as x becomes smaller. This is because a smaller x implies a larger value for the parameter d leading to larger delay as suggested by the delay bound (8) in Theorem 2. Thus, the 2-Hop Relay Algorithm is able to support all input rates within the network capacity with finite average delay. However, its delay performance is not necessarily the best. For example, when the input rate is small (say $\lambda = 0.1$ packets/slot), the average delay is more than 100 slots. Note that the 2-Hop Relay Algorithm makes scheduling decisions purely based on the current user locations and restricts all packets to at most 2 hops. It does not attempt to optimize the delay in the network. The delay performance may be improved using alternative scheduling strategies that do not restrict packets to at most 2 hops. For example, backlog aware scheduling and routing (e.g., [7]) or schemes that exploit the mobility pattern of the users (e.g., [15]) may offer better delay performance.

IV. MINIMUM ENERGY FUNCTION

We now investigate the minimum energy function of the cell-partitioned network under consideration. Recall that in our network model, each user either uses zero power or full power. Further, $R_1 (R_2)$ packets can be transmitted from the sender to the receiver in the same (adjacent) cell if the sender uses full power.

The minimum energy function $\Phi(\lambda)$ is defined as the minimum time average energy required to stabilize an input rate λ per user, considering all possible scheduling and routing algorithms that conform to the given network structure. We exactly compute this function for our network model. Specifically, we assume that all users receive packets at the same rate (i.e., $\lambda_i = \lambda$ for all i). Also, we consider the case when $R_1 \geq 2R_2$ ($\Phi(\lambda)$ for the case when $R_1 < 2R_2$ has a different expression, but the proof is similar).

Theorem 3: The minimum energy function $\Phi(\lambda)$ per user for the cell-partitioned network as described in Sec. II with $R_1 \geq 2R_2$ is a piecewise linear curve given by the following:

$$\Phi(\lambda) = \begin{cases} \frac{\lambda}{R_1} & \text{if } C_1 \\ \frac{q}{\theta} + \frac{2}{R_1}\Big(\lambda - \frac{2R_1 q}{2\theta}\Big) & \text{if } C_2 \\ \frac{p}{\theta} + \frac{1}{R_2}\Big(\lambda - \frac{R_1(p+q)}{2\theta}\Big) & \text{if } C_3 \\ \frac{p+q'}{\theta} + \frac{2}{R_2}\Big(\lambda - \frac{R_1(p+q)+2R_2q'}{2\theta}\Big) & \text{if } C_4 \end{cases}$$

where $C_1 \equiv 0 \leq \lambda < \frac{R_1 q}{\theta}, C_2 \equiv \frac{R_1 q}{\theta} \leq \lambda < \frac{R_1(p+q)}{2\theta}, C_3 \equiv \frac{R_1(p+q)}{2\theta} \leq \lambda < \frac{R_1(p+q)+2R_2q'}{2\theta}, C_4 \equiv \frac{R_1(p+q)+2R_2q'}{2\theta} \leq \lambda < \mu$. Thus, the network can stably support users simultaneously communicating at any rate $\lambda < \mu$ with an energy cost that can be pushed arbitrarily close to $\Phi(\lambda)$ (at the cost of increased delay). We prove the theorem in two parts. First, we establish the necessary condition by deriving a lower bound on the energy cost of *any* stabilizing algorithm. Then, we establish sufficiency by presenting a specific scheduling policy and showing that the average delay is bounded under that policy.

A. Proof of Necessity

Proof: Consider any scheduling strategy that stabilizes the system. Let $X_{ab}(T)$ denote the number of packets delivered by the strategy from sources to destinations in time interval $(0, T)$ that involves exactly a same cell and b adjacent cell transmissions. For simplicity, assume that the strategy is ergodic and yields well defined time average energy expenditure per user $\overline{e}$ and well defined time average values for x_{ab} where:

$$x_{ab} \triangleq \lim_{T\to\infty} \frac{X_{ab}(T)}{T} \tag{17}$$

The average energy cost per user $\overline{e}$ of this policy satisfies:

$$\overline{e} \geq \sum_{a,b} \Big(\frac{a}{R_1} + \frac{b}{R_2}\Big)\frac{x_{ab}}{N} \tag{18}$$

This follows by noting that enough packets may not be available during a transmission.

Note that $x_{00} = 0$, and so the only possible non-zero x_{ab} variables are for (a, b) pairs that are integers, non-negative, and such that $(a, b) \neq (0, 0)$. Let $x = (x_{ab})$ represent the collection of x_{ab} variables, and note that these variables must satisfy the constraint $x \in \Omega_0 \cap \Omega_1 \cap \Omega_2 \cap \Omega_3$, where the four constraint sets are defined below:

$$\Omega_0 \triangleq \left\{ x \,\middle|\, \sum_{(a,b)\neq(0,0)} x_{ab} = N\lambda \right\} \qquad \Omega_1 \triangleq \left\{ x \,\middle|\, \frac{x_{10}}{R_1} \leq c_1 \right\}$$

$$\Omega_2 \triangleq \left\{ x \,\middle|\, \frac{1}{R_1}\sum_a a x_{a0} \leq c_1 + c_2 \right\}$$

$$\Omega_3 \triangleq \left\{ x \,\middle|\, \frac{1}{R_1}\sum_a a x_{a0} + \frac{x_{01}}{R_2} \leq c_1 + c_2 + c_3 \right\}$$

where c_1 is the maximum rate of source-destination transmission opportunities in the same cell, $c_1 + c_2$ is the maximum rate of all possible same cell transmission opportunities and $c_1 + c_2 + c_3$ is the maximum rate of all same cell or source-destination adjacent cell transmission opportunities. Here, these quantities are summed over all cells. Using the definitions of p, q and q' from the statement of Theorem 1, we know that $c_1 = Cq, c_1 + c_2 = Cp, c_1 + c_2 + c_3 = C(p + q')$. For example, $(c_1 + c_2 + c_3)$ can be written as $\frac{1}{T}\sum_{t=0}^{T}\Big(X_1(t) + X_2(t) + X_3(t)\Big)$ where $X_1(t)$ is the maximum number of direct same cell opportunities, $X_2(t)$ is the maximum number of indirect same cell opportunities *given* all direct opportunities are used and $X_3(t)$ is the maximum number of direct adjacent cell opportunities *given* all same cell opportunities are used.

Since only one of these three opportunities can used is a given cell in a timeslot, the maximum total sum is fixed and hence $c_1 + c_2 + c_3 = C(p + q')$.

Define $f(x) \triangleq \sum_{a,b} \left(\frac{a}{R_1} + \frac{b}{R_2}\right) \frac{x_{ab}}{N}$, which is simply the right hand side of (18). Because $\overline{e} \geq f(x)$, and because $x \in \Omega_0 \cap \Omega_1 \cap \Omega_2 \cap \Omega_3$, we have:

$$\overline{e} \geq \inf_{x \in \Omega_0 \cap \Omega_1 \cap \Omega_2 \cap \Omega_3} f(x) \tag{19}$$

Furthermore, for any function $g(x)$ such that $g(x) \leq f(x)$ for all x, and for any set $\tilde{\Omega}$ that contains the set $\Omega_0 \cap \Omega_1 \cap \Omega_2 \cap \Omega_3$, we have:

$$\overline{e} \geq \inf_{x \in \tilde{\Omega}} g(x) \tag{20}$$

This follows because the function to be minimized is smaller, and the infimum is taken over a less restrictive set. We now define four new constraint sets $\tilde{\Omega}_0, \tilde{\Omega}_1, \tilde{\Omega}_2, \tilde{\Omega}_3$ as follows:

$$\tilde{\Omega}_0 \triangleq \Omega_0 \;\; \tilde{\Omega}_1 \triangleq \Omega_1 \;\; \tilde{\Omega}_2 \triangleq \left\{ x \,\middle|\, \frac{x_{10}}{R_1} + \frac{2}{R_1} \sum_{a \geq 2} x_{a0} \leq c_1 + c_2 \right\}$$

$$\tilde{\Omega}_3 \triangleq \left\{ x \,\middle|\, \frac{x_{10}}{R_1} + \frac{2}{R_1} \sum_{a \geq 2} x_{a0} + \frac{x_{01}}{R_2} \leq c_1 + c_2 + c_3 \right\}$$

It can be seen that each of $\Omega_0, \Omega_1, \Omega_2, \Omega_3$ is a subset of $\tilde{\Omega}_0, \tilde{\Omega}_1, \tilde{\Omega}_2, \tilde{\Omega}_3$. Therefore, $\Omega_0 \cap \Omega_1 \cap \Omega_2 \cap \Omega_3$ is a subset of $\tilde{\Omega}_0 \cap \tilde{\Omega}_1 \cap \tilde{\Omega}_2 \cap \tilde{\Omega}_3$. Note that since $\frac{2}{R_1} \leq \frac{1}{R_2}$, we have the following:

$$\frac{1}{R_1} < \frac{2}{R_1} \leq \frac{1}{R_2} < \frac{2}{R_2} \tag{21}$$

We now compute four different bounds for $\overline{e}$, each having the form $\overline{e} \geq \alpha\lambda + \beta$. These bounds define the four piecewise linear regions of $\Phi(\lambda)$.

1) First note that $f(x) \geq \frac{1}{R_1} \sum_{a,b} \frac{x_{ab}}{N}$. This follows from the definition of $f(x)$. Therefore taking $g(x) = \frac{1}{R_1} \sum_{a,b} \frac{x_{ab}}{N}$, we have:

   $$\overline{e} \geq \inf_{x \in \tilde{\Omega}_0} \frac{1}{R_1} \sum_{a,b} \frac{x_{ab}}{N}$$

   Because $\tilde{\Omega}_0$ is given by $\sum_{a,b} x_{ab} = N\lambda$, the above infimum is equal to $\frac{\lambda}{R_1}$. Thus, we have our first linear constraint for any algorithm that yields a time average energy of $\overline{e}$:

   $$\overline{e} \geq \frac{\lambda}{R_1} \tag{22}$$

2) Next note that $f(x) \geq \frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{\substack{a,b \\ (a,b) \neq (1,0)}} \frac{x_{ab}}{N}$. This is because $\frac{a}{R_1} + \frac{b}{R_2} \geq \frac{2}{R_1}$ for any non-negative integer pair (a, b) such that $(a, b) \neq \{(0, 0), (1, 0)\}$ (using (21)). Therefore, taking this lower bound of $f(x)$ as $g(x)$, we have:

   $$\overline{e} \geq \inf_{x \in \tilde{\Omega}_0 \cap \tilde{\Omega}_1} \left[\frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{\substack{a,b \\ (a,b) \neq (1,0)}} \frac{x_{ab}}{N} \right]$$

   The right hand side is equal to the solution of the following:

   $$\begin{aligned} \text{Minimize:} \quad & \frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{\substack{a,b \\ (a,b) \neq (1,0)}} \frac{x_{ab}}{N} \\ \text{Subject to:} \quad & \sum_{a,b} x_{ab} = N\lambda \\ & \frac{x_{10}}{R_1} \leq c_1 \end{aligned}$$

   The above optimization is equivalent to minimizing $\frac{x_{10}}{NR_1} + \frac{2}{NR_1}(N\lambda - x_{10})$ subject to $\frac{x_{10}}{R_1} \leq c_1$. The solution is clearly to choose $x_{10} = R_1 c_1$, and hence we have:

   $$\overline{e} \geq \frac{2\lambda}{R_1} - \frac{c_1}{N} = \frac{q}{\theta} + \frac{2}{R_1}\Big(\lambda - \frac{2R_1 q}{2\theta}\Big) \tag{23}$$

3) Next we have

   $$f(x) \geq \frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{a \geq 2} \frac{x_{a0}}{N} + \frac{1}{R_2} \sum_{\substack{a,b \\ b \neq 0}} \frac{x_{ab}}{N}$$

   which follows from the definition of $f(x)$ and because $\frac{1}{R_2} \leq \frac{b}{R_2}$ for all positive $b \geq 1$. Thus, taking this lower bound of $f(x)$ as $g(x)$, we have:

   $$\overline{e} \geq \inf_{x \in \tilde{\Omega}_0 \cap \tilde{\Omega}_1 \cap \tilde{\Omega}_2} \left[\frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{a \geq 2} \frac{x_{a0}}{N} + \frac{1}{R_2} \sum_{\substack{a,b \\ b \neq 0}} \frac{x_{ab}}{N} \right]$$

   This is equivalent to the following minimization:

   $$\begin{aligned} \text{Minimize:} \quad & \frac{x_{10}}{NR_1} + \frac{2}{NR_1} \sum_{a \geq 2} x_{a0} \\ & + \frac{1}{NR_2}\Big(N\lambda - x_{10} - \sum_{a \geq 2} x_{a0}\Big) \\ \text{Subject to:} \quad & \frac{x_{10}}{R_1} \leq c_1 \\ & \frac{x_{10}}{R_1} + \frac{2}{R_1} \sum_{a \geq 2} x_{a0} \leq c_1 + c_2 \end{aligned}$$

   where we have aggregated the constraint $\sum_{a,b} x_{ab} = N\lambda$ into the objective. The coefficients multiplying x_{10} and $\sum_{a \geq 2} x_{a0}$ are both negative, so that the above optimization is solved when $x_{10} + 2\sum_{a \geq 2} x_{a0} = R_1(c_1 + c_2)$. Similarly, it can be shown that above optimization is solved when $x_{10} = R_1 c_1$. This yields:

   $$\begin{aligned} \overline{e} &\geq \frac{\lambda}{R_2} + \frac{(c_1 + c_2)}{N} - \frac{R_1}{NR_2}\Big(c_1 + \frac{c_2}{2}\Big) \\ &= \frac{p}{\theta} + \frac{1}{R_2}\Big(\lambda - \frac{R_1(p + q)}{2\theta}\Big) \end{aligned} \tag{24}$$

4) Finally, note that

   $$f(x) \geq \frac{x_{10}}{NR_1} + \frac{2}{R_1} \sum_{a \geq 2} \frac{x_{a0}}{N} + \frac{x_{01}}{NR_2} + \frac{2}{R_2} \sum_{b \geq 2} \frac{x_{ab}}{N}$$

   which follows from the definition of $f(x)$ as well as because $\frac{2}{R_2} \leq \frac{b}{R_2}$ for all $b \geq 2$. Taking this lower bound of $f(x)$ as $g(x)$, we have:

$$\overline{e} \geq \inf_{x\in\tilde{\Omega}} \left[\frac{x_{10}}{NR_1} + \frac{2}{R_1}\sum_{a\geq 2}\frac{x_{a0}}{N} + \frac{x_{01}}{NR_2} + \frac{2}{R_2}\sum_{b\geq 2}\frac{x_{ab}}{N}\right]$$

where $\tilde{\Omega} = \tilde{\Omega}_0 \cap \tilde{\Omega}_1 \cap \tilde{\Omega}_2 \cap \tilde{\Omega}_3$. This is equivalent to the following minimization (using $\sum_{a,b} x_{ab} = N\lambda$):

$$\begin{aligned}
\text{Minimize: } & \frac{x_{10}}{NR_1} + \frac{2}{NR_1}\sum_{a\geq 2} x_{a0} + \frac{x_{01}}{NR_2} \\
& + \frac{2}{NR_2}\Big(N\lambda - x_{10} - \sum_{a\geq 2} x_{a0} - x_{01}\Big) \\
\text{Subject to: } & \frac{x_{10}}{R_1} \leq c_1 \\
& \frac{x_{10}}{R_1} + \frac{2}{R_1}\sum_{a\geq 2} x_{a0} \leq c_1 + c_2 \\
& \frac{x_{10}}{R_1} + \frac{2}{R_1}\sum_{a\geq 2} x_{a0} + \frac{x_{01}}{R_2} \leq c_1 + c_2 + c_3
\end{aligned}$$

Letting $y = \sum_{a\geq 2} x_{a0}$ and simplifying the optimization metric, the above optimization is equivalent to:

$$\begin{aligned}
\text{Minimize: } & \frac{x_{10}}{N}\Big(\frac{1}{R_1} - \frac{2}{R_2}\Big) + \frac{y}{N}\Big(\frac{2}{R_1} - \frac{2}{R_2}\Big) \\
& - \frac{x_{01}}{NR_2} + \frac{2\lambda}{R_2} \\
\text{Subject to: } & \frac{x_{10}}{R_1} \leq c_1 \\
& \frac{x_{10}}{R_1} + \frac{2y}{R_1} \leq c_1 + c_2 \\
& \frac{x_{10}}{R_1} + \frac{2y}{R_1} + \frac{x_{01}}{R_2} \leq c_1 + c_2 + c_3
\end{aligned}$$

The above optimization is solved when $x_{10} = R_1 c_1$, $x_{10} + 2y = R_1(c_1 + c_2)$ and $x_{01} = R_2 c_3$. We thus have:

$$\begin{aligned}
\overline{e} &\geq \frac{2\lambda}{R_2} + \frac{(c_1 + c_2)}{N} - \frac{R_1}{NR_2}(2c_1 + c_2) - \frac{c_3}{N} \\
&= \frac{p + q'}{\theta} + \frac{2}{R_2}\Big(\lambda - \frac{R_1(p+q) + 2R_2 q'}{2\theta}\Big) \qquad (25)
\end{aligned}$$

The necessary set of conditions for $\Phi(\lambda)$ function are obtained by combining these four bounds. ■

B. Proof of Sufficiency

Now we present an algorithm that makes stationary, randomized scheduling decisions independent of the actual queue backlog values and show that for any feasible input rate $\lambda < \mu$, its average energy cost can be pushed arbitrarily close to the minimum value $\Phi(\lambda)$ with bounded delay. However, the delay bound grows asymptotically as the average energy is pushed closer to the minimum value. Similar to the capacity achieving 2-Hop Relay Algorithm, this algorithm also restricts packets to at most 2 hops. However, the difference lies in that it *greedily* chooses transmission opportunities involving smaller energy cost over other higher cost opportunities. An opportunity with higher cost is used *only* when the given input rate cannot be supported using all of the low cost opportunities. Thus, depending on the input rate λ, the algorithm uses only a subset of the transmission opportunities as follows.

1) If $0 \leq \lambda < \frac{2R_1 q}{2\theta}$, all packets are sent using only source-destination transmission opportunities in the same cell.
2) If $\frac{2R_1 q}{2\theta} \leq \lambda < \frac{R_1(p+q)}{2\theta}$, all packets are sent either using source-destination transmission opportunities in the same cell or source-relay and relay-destination transmission opportunities in the same cell.
3) If $\frac{R_1(p+q)}{2\theta} \leq \lambda < \frac{R_1(p+q)+2R_2q'}{2\theta}$, all packets are sent using same cell transmissions (in either direct transmission or relay modes), or adjacent cell source-destination transmission opportunities.
4) And finally, when $\frac{R_1(p+q)+2R_2q'}{2\theta} \leq \lambda < \mu$, all transmission opportunities that restrict packets to at most 2 hops are used.

To make the presentation simpler, in the following, we only discuss the case where $\frac{R_1 q}{\theta} < \lambda < \frac{R_1(p+q)}{2\theta}$. The basic idea and performance analysis for the other cases are similar.

Let $\lambda = \frac{R_1 q}{\theta} + \rho\frac{R_1(p-q)}{2\theta}$ where $0 < \rho < 1$ is a given constant. Also define a control parameter β (where $1 < \beta < 1/\rho$) that is input to the algorithm. This parameter affects an energy-delay tradeoff as shown in Theorem 4.

Minimum Energy Algorithm: Every timeslot, for all cells, do the following:

1) If there exists a source-destination pair in the cell, randomly choose such a pair (uniformly over all such pairs in the cell). If the source has new packets for the destination, transmit at rate R_1. Else remain idle.
2) If there is no source-destination pair in the cell but there are at least 2 users in the cell, then with probability $\beta\rho$, decide to use the same cell relay transmission opportunity as described in the next step. Else remain idle.
3) If decide to use the same cell relay transmission opportunity in step (2), randomly designate one user as the sender and another as the receiver. Then with probability $\frac{1-\delta}{2}$ (where $0 < \delta < 1$ and $\delta = \delta(\beta)$ to be determined later) perform the first action below. Else, perform the second.
   a) *Send new Relay packets in same cell*: If the transmitter has new packets for its destination, transmit at rate R_1. Else remain idle.
   b) *Send Relay packets to their Destination in same cell*: If the transmitter has packets for the receiver, transmit at rate R_1. Else remain idle.

Note that the above algorithm does not use any adjacent cell transmission opportunities. All packets are sent over at most 2 hops using only same cell transmissions. We now analyze the performance of this algorithm.

Theorem 4: For the cell partitioned network (with N nodes and C cells) as described in Sec. II, with minimum energy function $\Phi(\lambda)$ as described above, and user mobility model as described in Sec. II-B, the average energy cost $\overline{e}$ of the Minimum Energy Algorithm with input rate λ for each user such that $\lambda = \frac{R_1 q}{\theta} + \rho\frac{R_1(p-q)}{2\theta}$ (where $0 < \rho < 1$), a control parameter β (where $1 < \beta < 1/\rho$), and with $\delta = \frac{\beta-1}{2\beta}$ satisfies:

$$\overline{e} = \Phi(\lambda) + (\beta - 1)\rho\Big(\frac{p-q}{\theta}\Big) \qquad (26)$$

and the average packet delay $\overline{D}$ satisfies:

$$\overline{D} \leq \frac{4BN\theta(2d+1)}{\lambda R_1(p-q)\rho(\beta-1)} \tag{27}$$

where B is a constant given by (11) and d is a finite integer that is related to the mixing time of the joint user mobility process and is given by $d = \left\lceil \frac{\log\left(\frac{4N^2(p+q)\alpha\beta}{(p-q)\rho(\beta-1)}\right)}{\log(1/\gamma)} \right\rceil$.

From the above, it can be seen that the control parameter β allows a $(O(\beta-1), O(1/(\beta-1)))$ tradeoff between the average energy cost and the average delay bound. Specifically, the average energy cost $\overline{e}$ can be pushed arbitrarily close to $\Phi(\lambda)$ by pushing β closer to 1. However, this increases the bound on $\overline{D}$ as $1/(\beta-1)$.

Proof: The proof is similar to the proof of Theorem 2 and is given in Appendix C. ■

V. CAPACITY GAINS BY NETWORK CODING

Here, we show an example where the network capacity can be strictly improved by making use of network coding in conjunction with the wireless broadcast advantage. Specifically, consider a network with 6 nodes and 4 cells. Suppose the steady-state location distribution for all nodes is uniform over all cells. Thus, $\pi_c = 1/4$ for all c. The one-to-one traffic pairing is given by $1 \leftrightarrow 2, 3 \leftrightarrow 4, 5 \leftrightarrow 6$. Let $R_1 = 1$ and $R_2 = 0$. Thus, this example only allows same cell transmissions. We further assume that when a node in a cell transmits, all other nodes in that cell receive that packet. Note that the 2-Hop Relay Algorithm presented in Sec. III-B does not make use of this feature.

Using Theorem 1, the network capacity under the model presented in Sec. II can be computed. Specifically, the network capacity is given by $\mu = \frac{q+p}{2\theta}$ packets/slot per node where $\theta = \frac{6}{4}$ and using (2), we have $q = 1 - \left(1 - \frac{1}{16}\right)^3$ and $p = 1 - \left(1 - \frac{1}{4}\right)^6 - \frac{6}{4}\left(1 - \frac{1}{4}\right)^5$.

We now show how network coding can be used to achieve a throughput that is strictly higher than μ. First we define 4 distinct configurations of the nodes. In configuration I, nodes $1, 4,$ and 5 are in the same cell and the other nodes can be in any of the remaining cells (but not in the same cell as nodes $1, 4,$ and 5). Note that this cell can be any one of the 4 cells. From the assumption about the node mobility process, the steady-state probability of configuration I is given by $\nu \triangleq 4 \times (\frac{1}{4})^3 \times (\frac{3}{4})^3$. In configuration II, nodes $2, 3,$ and 5 are in the same cell and the other nodes can be in any of the remaining cells (but not in the same cell as nodes $2, 3,$ and 5). In configuration III, nodes $2, 4,$ and 5 are in the same cell and the other nodes can be in any of the remaining cells (but not in the same cell as nodes $2, 4,$ and 5). Finally, in configuration IV, nodes $1, 3,$ and 5 are in the same cell and the other nodes could be in any of the remaining cells (but not in the same cell as nodes $1, 3,$ and 5). Note that these configurations cannot occur simultaneously as each consists of node 5. Further, the steady-state probability of each configuration is given by ν.

In the following, we will modify the 2-Hop Relay Algorithm of Sec. III-B when one of these configurations occur in any cell and demonstrate an improvement in the throughput of nodes $1, 2, 3$ and 4 over μ. For each configuration, we will only focus on the transmissions in the cell with the three nodes that define that configuration. The 2-Hop Relay Algorithm for the other cells remains the same.

Note that under each configuration, there are no source-destination pairs in the cell of interest. Thus, under the 2-Hop Relay Algorithm, a node is selected as the transmitter with probability $\frac{1}{3}$ while the remaining two nodes are equally likely to be selected as the receiver. Further, the transmitter is scheduled to transmit a new packet to the receiver with probability $\frac{1-\delta}{2}$ and is scheduled to transmit a relay packet to the receiver with probability $\frac{1+\delta}{2}$. Thus, in each configuration, each of the two nodes other than node 5 is scheduled to transmit a new packet to node 5 with probability $\frac{1}{3} \times \frac{1}{2} \times \frac{(1-\delta)}{2} = \frac{(1-\delta)}{12}$. Also, in each configuration, node 5 is scheduled to transmit a relay packet to each of the other two nodes in the cell with probability $\frac{1}{3} \times \frac{1}{2} \times \frac{(1+\delta)}{2} = \frac{(1+\delta)}{12}$. Adding the probabilities associated with these four scheduling decisions yields

$$\frac{(1-\delta)}{12} + \frac{(1-\delta)}{12} + \frac{(1+\delta)}{12} + \frac{(1+\delta)}{12} = \frac{1}{3} \tag{28}$$

We now modify the 2-Hop Relay Algorithm to take advantage of network coding. For all configurations other than the four as defined above, the algorithm remains the same. However, in each of the configurations $\text{I}, \text{II}, \text{III}, \text{IV}$, we change the probability of scheduling a node to transmit a new packet (for relaying) to node 5 from $\frac{(1-\delta)}{12}$ to $\frac{1}{3} \times \frac{(1-\epsilon)}{3} = \frac{(1-\epsilon)}{9}$ where $0 < \epsilon < 1$. Also, node 5 is scheduled to transmit a relay packet to the other two nodes in the cell with probability $\frac{1}{3} \times \frac{(1+2\epsilon)}{3} = \frac{(1+2\epsilon)}{9}$. However, whenever node 5 has at least one packet for each of the two other nodes, it broadcasts a XOR of two packets destined for these nodes in a single transmission. If node 5 does not have at least one packet for each of the two other nodes, it would simply transmit a regular packet (if available). Note that under the original 2-Hop Relay Algorithm, the two scheduling decisions of node 5 transmitting a relay packet to the other two nodes are taken with probability $\frac{(1+\delta)}{12}$ each. These are now replaced by a *single* scheduling decision of node 5 broadcasting a XORed relay packet and this has probability $\frac{(1+2\epsilon)}{9}$. The probabilities associated with the other scheduling decisions under this modified algorithm remain the same as the original 2-Hop Relay Algorithm. The sum of probabilities associated with the modified scheduling decisions as described above is given by

$$\frac{(1-\epsilon)}{9} + \frac{(1-\epsilon)}{9} + \frac{(1+2\epsilon)}{9} = \frac{1}{3} \tag{29}$$

This is the same as (28). Thus, it can be seen that the probabilities of all scheduling decisions under the modified algorithm sum to 1.

To see how the nodes can recover the original packets from the XORed packet, we further classify each configuration into type A, B and C depending on the scheduling decision as shown in Fig. 3. The configurations of type A and B correspond to the scheduling decisions in which a node is scheduled to transmit a new packet (for relaying) to node 5. The configurations of type C correspond to the scheduling

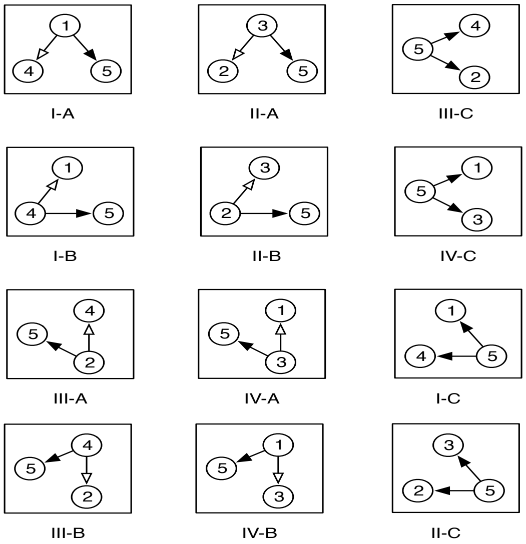

Fig. 3. An example showing capacity gains possible by using network coding in conjunction with the wireless broadcast advantage.

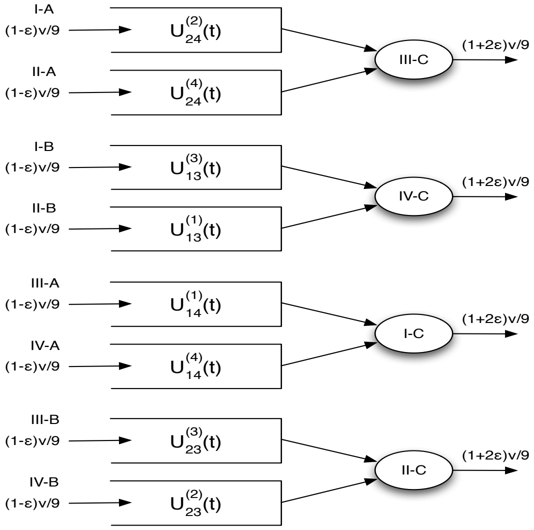

Fig. 4. Additional relay queues at node 5 under the network coding enhanced 2-Hop Relay Algorithm that is used in configurations I, II, III, IV.

decisions in which node 5 is scheduled to transmit relay packets to the other two nodes (either as a network coded XOR packet whenever possible or a regular packet). In each configuration of type A or B, whenever a new packet is transmitted by a node to node 5 for relaying, the other node overhears the packet and stores a copy. For example, in Fig. I-A, when node 1 transmits a new packet (destined for node 2) to node 5, node 4 overhears this transmission and stores a copy of this packet. Similarly, in II-A, when node 3 transmits a new packet (destined for node 4) to node 5, node 2 overhears this transmission and stores a copy of this packet. In each configuration of type C, whenever node 5 has at least one packet for each of the two other nodes, note that each of these two nodes already has a copy of the packet destined for the other node (that it obtained by overhearing earlier in a type A or B configuration). Therefore, when node 5 transmits a XOR packet, both of these nodes can recover the original packets destined for them by using the side information already available to them in the form of previously overheard and stored packets. For example, in III-C, node 5 is in the same cell as nodes 2 and 4 and suppose it has a packet for each of them. Then, node 2 must have the packet that is destined for node 4 that it overheard in II-A. Similarly, node 4 must have the packet that is destined for node 2 that it overheard in I-A. Thus, when node 5 broadcasts a XOR packet in a single transmission, both nodes 2 and 4 can retrieve their desired packets. Thus, this single transmission effectively delivers two packets. Note that under a scheme that does not allow mixing of packets, at most one packet can be transmitted per transmission.

To demonstrate gains in throughput under this "network coding enhanced" 2-Hop Relay Algorithm, we define the following additional relay queues at node 5 as shown in Fig. 4. Arrivals to and departures from these queues happen only when scheduling decisions corresponding to the 12 configurations in Fig. 3 are made according to the enhanced 2-Hop Relay Algorithm. $U_{ij}^{(i)}(t)$ and $U_{ij}^{(j)}(t)$ refer to the queue of packets destined for nodes i and j respectively that will be network coded whenever possible. Fig. 4 shows the arrival rates and the corresponding configurations (when arrivals happen to these queues) as well as the service rates and corresponding configurations (when packets are served from these queues). Note that each queue has an arrival rate of $\frac{(1-\epsilon)\nu}{9}$ and sees a service rate of $\frac{(1+2\epsilon)\nu}{9}$. Since $(1+2\epsilon) > (1-\epsilon)$, all these queues are stable. The additional throughput for nodes $1, 2, 3$ and 4 over the 2-Hop Relay Algorithm without network coding is given by $\left[\frac{2(1-\epsilon)}{9} - \frac{2(1-\delta)}{12}\right]\nu$ packets/slot. This is strictly positive for any $0 < \epsilon < \frac{1}{4}$. For example, by choosing $\epsilon = \frac{1}{8}$, a throughput gain of $\frac{\nu}{36}$ packets/slot is achievable. Thus, the capacity can be strictly increased over a scheme that is restricted to pure routing.

VI. CONCLUSIONS

In this work, we investigated two quantities of fundamental interest in a delay-tolerant mobile ad hoc network: the network capacity and the minimum energy function. Using a cell-partitioned model of the network, we obtained *exact* expressions for both these quantities in terms of the network parameters (number of nodes N and number of cells C) and the steady-state location distribution of the mobility process. Our results hold for general mobility processes (possibly non-uniform and non-i.i.d.) and our analytical technique can be extended to other models with additional scheduling constraints.

We also proposed two simple scheduling strategies that can achieve these bounds arbitrarily closely at the cost of an increased delay. Both these schemes restrict packets to at most 2 hops and make scheduling decisions purely based on the current user locations and independent of the actual queue backlogs. For both schemes, we computed bounds on the average packet delay using a Lyapunov drift technique.

In this paper, we have focused on network control algorithms that operate according to the network structure as presented in Sec. II. We assumed that the packets themselves are kept intact and are not combined or network coded. As shown in the example in Sec. V, it is possible to increase the network capacity by making use of network coding and the wireless broadcast feature. An interesting future direction of this research is to determine the exact capacity region with such enhanced control options.

APPENDIX A
PROOF OF LEMMA 1

Here, we prove the bound in Lemma 1. We have

$$\mathbb{E}\left\{f(\vec{\chi}(t+d))|\vec{\chi}(t)\right\} = \sum_{\vec{c}} f(\vec{c}) \times Pr\{\vec{\chi}(t+d) = \vec{c}|\vec{\chi}(t)\}$$

$$= \sum_{c_1,c_2,\ldots,c_N} f(c_1,c_2,\ldots,c_N)\Big[\prod_{i=1}^{N} Pr\{\chi_i(t+d) = c_i|\vec{\chi}(t)\}\Big]$$

$$\geq \sum_{c_1,c_2,\ldots,c_N} f(c_1,c_2,\ldots,c_N)\Big[\prod_{i=1}^{N} \pi_{c_i}(1-\alpha\gamma^d)\Big]$$

$$= \sum_{c_1,c_2,\ldots,c_N} f(c_1,c_2,\ldots,c_N)\Big(\prod_{i=1}^{N} \pi_{c_i}\Big)(1-\alpha\gamma^d)^N$$

$$\geq \sum_{c_1,c_2,\ldots,c_N} f(c_1,c_2,\ldots,c_N)\Big(\prod_{i=1}^{N} \pi_{c_i}\Big)(1-2N\alpha\gamma^d)$$

$$= f_{av}(1-2N\alpha\gamma^d)$$

where step two follows from the independence of node mobility processes, step three follows from (1) and the second last step uses the inequality $(1-\alpha\gamma^d)^N \geq (1-2N\alpha\gamma^d)$. This can be shown by induction as follows. This holds for $N = 1$. Suppose it holds for some integer $i > 1$, i.e., $(1-\alpha\gamma^d)^i \geq (1-2i\alpha\gamma^d)$. Then, we have

$$(1-\alpha\gamma^d)^{i+1} = (1-\alpha\gamma^d)^i(1-\alpha\gamma^d) \geq (1-2i\alpha\gamma^d)(1-\alpha\gamma^d) \geq (1-2(i+1)\alpha\gamma^d)$$

The upper bound can be shown similarly, except that we use the inequality $(1+\alpha\gamma^d)^N \leq (1+2N\alpha\gamma^d)$ for all $N \geq 2$ whenever d is such that $\alpha\gamma^d < 1/N^2$. To show this, let $\alpha\gamma^d = c/N^2$ where $0 < c < 1$. Note that $0 < c/N < 1$. Then

$$(1+\alpha\gamma^d)^N$$

$$= 1 + N\alpha\gamma^d + \frac{N(N-1)}{2}(\alpha\gamma^d)^2 + \ldots + (\alpha\gamma^d)^N$$

$$< 1 + \frac{c}{N} + \Big(\frac{c}{N}\Big)^2 + \ldots + \Big(\frac{c}{N}\Big)^N < \frac{1}{1-\frac{c}{N}} = \frac{N}{N-c}$$

$$< 1 + \frac{c}{N-1} = 1 + \frac{N^2\alpha\gamma^d}{N-1} \leq 1 + 2N\alpha\gamma^d \qquad \forall N \geq 2$$

APPENDIX B
DERIVATION OF PROBABILITY EXPRESSIONS

In what follows, we will use the linearity of expectations property to compute the probability expressions in (2).

Derivation of q: Let $I_c(t)$ be an indicator variable that is 1 if there is a source-destination pair in cell c in slot t in the steady-state. Then the expected number of cells with a source-destination pair is given by $\mathbb{E}\left\{\sum_{c=1}^{C} I_c(t)\right\}$. By linearity of expectations, this is equal to $\sum_{c=1}^{C} \mathbb{E}\left\{I_c(t)\right\}$. To compute $\mathbb{E}\left\{I_c(t)\right\}$ for any cell c, note that by the independence of user mobility processes, π_c^2 is the probability of finding any particular source-destination pair in cell c in the steady-state. Since there are $N/2$ such pairs and they occur independent of each other, the probability of finding no source-destination pair in cell c in the steady-state is given by $(1-\pi_c^2)^{N/2}$. Thus, the probability of finding *at least* 1 source-destination pair is $1-(1-\pi_c^2)^{N/2}$. Using this, we get $q = \frac{1}{C}\sum_{c=1}^{C}(1-(1-\pi_c^2)^{N/2})$.

Derivation of p: To compute the probability of finding at least 2 users in a cell c, we note that this can be obtained by first computing the probabilities of finding no user and exactly 1 user in cell c and then subtracting these from 1. These are given by $(1-\pi_c)^N$ and $\binom{N}{1}\pi_c(1-\pi_c)^{N-1}$ respectively. Using this, we get $p = \frac{1}{C}\sum_{c=1}^{C}(1-(1-\pi_c)^N - N\pi_c(1-\pi_c)^{N-1})$.

Derivation of q': The probability of finding exactly 1 user in cell c is given by $\binom{N}{1}\pi_c(1-\pi_c)^{N-1}$. The probability of finding its destination in an adjacent cell *given that* it is not it cell c is given by $\frac{1}{1-\pi_c}\sum_{i\in\mathcal{B}_c}\pi_i$ which we have defined as $\Pi_{adj}(c)$. Using this, we get $q' = \frac{1}{C}\sum_{c=1}^{C}(\Pi_{adj}(c)N\pi_c(1-\pi_c)^{N-1})$.

Derivation of p': Given that there is exactly 1 user in cell c, the probability that at least 1 of the remaining $N-1$ users is in an adjacent cell is given by $1-(1-\Pi_{adj}(c))^{N-1}$. Thus, we get $p' = \frac{1}{C}\sum_{c=1}^{C}(1-(1-\Pi_{adj}(c))^{N-1})N\pi_c(1-\pi_c)^{N-1}$.

Derivation of q'': We first compute the probability of finding i users in cell c such that there are no source-destination pairs. Clearly, $1 \leq i \leq \frac{N}{2}$ since there must be at least 1 source-destination pair for $i > \frac{N}{2}$. Next, note that $2^i\frac{\binom{N/2}{i}}{\binom{N}{i}}$ is the probability of finding no source-destination pair in a cell *given that* there are i users in that cell. $\binom{N}{i}\pi_c^i(1-\pi_c)^{N-i}$ is the probability of having i users in cell c. Finally, the probability that there is at least 1 node in an adjacent cell that will make a source-destination pair with one of these i nodes *given that* it is not in cell c is given by $(1-(1-\Pi_{adj}(c))^i)$. Combining all these, we get

$$q'' = \frac{1}{C}\sum_{c=1}^{C}\sum_{i=1}^{N/2} 2^i\binom{N/2}{i}\pi_c^i(1-\pi_c)^{N-i}(1-(1-\Pi_{adj}(c))^i)$$

Derivation of p'': Similar to the derivation of q'', the probability of finding i users in cell c such that there are no source-destination pairs in cell c as well as any adjacent cells is given by $2^i\binom{N/2}{i}\pi_c^i(1-\pi_c)^{N-i}(1-\Pi_{adj}(c))^i$. Since we also want at least 2 users in cell c, we sum from $i = 2$ to $N/2$. This yields

$$p'' = \frac{1}{C}\sum_{c=1}^{C}\sum_{i=2}^{N/2} 2^i\binom{N/2}{i}\pi_c^i(1-\pi_c)^{N-i}(1-\Pi_{adj}(c))^i$$

APPENDIX C
PROOF OF THEOREM 4

Here, we establish the bounds (26) and (27).

When $\frac{R_1 q}{\theta} < \lambda < \frac{R_1(p+q)}{2\theta}$, under the Minimum Energy Algorithm, all transmissions are either same cell direct transmissions or same cell relay transmissions. Specifically, each user either transmits directly to its destination or transmits new packets to a relay or transmits relayed packets to their destination in the same cell. Each such transmission involves one unit of energy cost and therefore the average energy cost per user $\overline{e}$ can be expressed in terms of the rates of these transmission opportunities. The rate at which same cell direct transmissions are scheduled is given by Cq. The rate at which same cell relay transmissions are scheduled is given by $\beta\rho C(p-q)$. Thus, we have:

$$\begin{aligned}\overline{e} &= \frac{1}{N}\Big[Cq + \beta\rho C(p-q)\Big] = \frac{q}{\theta} + \rho\frac{p-q}{\theta} + (\beta-1)\rho\frac{p-q}{\theta}\\ &= \Phi(\lambda) + (\beta-1)\rho\Big(\frac{p-q}{\theta}\Big)\end{aligned}$$

Thus, $\overline{e}$ can be pushed arbitrarily close to $\Phi(\lambda)$ by choosing β close to 1.

The delay of the Minimum Energy Algorithm can be analyzed using a procedure similar to the one used in the proof of Theorem 2. We first evaluate bounds on the expression in (12) by computing the steady-state service rates $\overline{\mu}_{ib}^{(c)}, \overline{\mu}_{ai}^{(c)}$ achieved by the Minimum Energy Algorithm. We have the following 2 cases:

1) Node i generates type c packets: In this case, $\mathbb{E}\left\{A_i^{(c)}(t)\right\} = \lambda$ and $\sum_a \mu_{ai}^{(c)}(t) = 0$. To calculate $\sum_b \overline{\mu}_{ib}^{(c)}$, define r_1, r_2, r_3 similar to that in the proof of Theorem 2. Then, the total rate of transmission over the network is given by $N(r_1 + r_2 + r_3)$. Similar to Theorem 2, we have $r_2 = \frac{1-\delta}{1+\delta} r_3$. Since only same cell direct transmissions are used, we have $Nr_1 = CR_1 q$. Also, a same cell relay transmission is scheduled with probability $\beta\rho$ whenever there is no source-destination pair in the cell but there are at least 2 users in the cell, Thus, the sum total transmissions in the network can be expressed in terms of the quantities p and q as $N(r_1 + r_2 + r_3) = C(R_1 q + R_1\beta\rho(p-q))$. Solving for r_1, r_2, r_3, we have:

$$\begin{aligned} r_1 &= \frac{R_1 q}{\theta}, r_2 = \frac{R_1(p-q)(1-\delta)\beta\rho}{2\theta}\\ r_3 &= \frac{R_1(p-q)(1+\delta)\beta\rho}{2\theta} \end{aligned} \tag{30}$$

Therefore, we have:

$$\sum_b \overline{\mu}_{ib}^{(c)} = r_1 + r_2 = \frac{R_1 q}{\theta} + \frac{R_1(p-q)(1-\delta)\beta\rho}{2\theta}$$

Let $\delta = \frac{\beta-1}{2\beta}$ and $\alpha\gamma^d = \frac{(p-q)\rho\delta}{2(p+q)N^2} = \frac{(p-q)\rho(\beta-1)}{4\beta(p+q)N^2} < \frac{1}{N^2}$. Note that this choice of δ can be shown to represent a valid probability, because $1 < \beta < \frac{1}{\rho} \Rightarrow 0 < \frac{1}{2} - \frac{1}{2\beta} < \frac{1}{2} - \frac{\rho}{2} \Rightarrow 0 < \delta < 1$. Then, using (13), the last term of (12) under this case can be expressed as:

$$\begin{aligned} &\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\} \geq\\ &(r_1 + r_2)(1 - 2N\alpha\gamma^d) - \lambda \geq (r_1 + r_2) - \frac{R_1(p-q)\rho\delta}{2\theta N} - \lambda\\ &= \frac{R_1(p-q)\rho}{2\theta}\Big[(1-\delta)\beta - \frac{\delta}{N} - 1\Big] \geq \frac{R_1(p-q)\rho(\beta-1)}{8\theta} \end{aligned}$$

where we used the relations $\lambda = r_1 + \frac{r_2}{(1-\delta)\beta}$, $(r_1 + r_2)2N\alpha\gamma^d \leq \frac{R_1(p-q)\rho\delta}{2\theta N}$ and $(1-\delta)\beta - \frac{\delta}{N} - 1 \geq \frac{\beta-1}{4}$. These can be shown as follows. Using (30), we have $\lambda = \frac{R_1 q}{\theta} + \rho\frac{R_1(p-q)}{2\theta} = r_1 + \frac{r_2}{(1-\delta)\beta}$. Next:

$$\begin{aligned} &(r_1 + r_2)2N\alpha\gamma^d = \Big(\frac{R_1 q}{\theta} + \frac{R_1(p-q)(1-\delta)\beta\rho}{2\theta}\Big)\frac{(p-q)\rho\delta}{(p+q)N}\\ &< \Big(\frac{R_1 q}{\theta} + \frac{R_1(p-q)}{2\theta}\Big)\frac{(p-q)\rho\delta}{(p+q)N} \qquad \text{(since } (1-\delta)\beta\rho < 1)\\ &= \frac{R_1(p-q)\rho\delta}{2\theta N} \end{aligned}$$

Finally, using $\delta = \frac{\beta-1}{2\beta}$, we have:

$$\begin{aligned} (1-\delta)\beta - \frac{\delta}{N} - 1 &= \frac{\beta+1}{2} - \frac{\delta}{N} - 1 \geq \frac{\beta-1}{2} - \frac{\delta}{2}\\ &= \frac{\beta-1}{2} - \frac{\beta-1}{4\beta} \geq \frac{\beta-1}{4} \end{aligned}$$

2) Node i relays type c packets: From our traffic model, we know that in this case $A_i^{(c)}(t) = 0$ for all t. To compute $\sum_b \overline{\mu}_{ib}^{(c)}$ and $\sum_a \overline{\mu}_{ai}^{(c)}$, note that the Minimum Energy Algorithm schedules relay transmissions such that all $N-2$ relay packet types are equally likely. Thus we have:

$$\sum_b \overline{\mu}_{ib}^{(c)} = \frac{r_3}{N-2}, \quad \sum_a \overline{\mu}_{ai}^{(c)} = \frac{r_2}{N-2}$$

Let $\delta = \frac{\beta-1}{2\beta}$ and $\alpha\gamma^d = \frac{(p-q)\rho\delta}{2(p+q)N^2} = \frac{(p-q)\rho(\beta-1)}{4\beta(p+q)N^2} < \frac{1}{N^2}$. Then, using (13), (14), the last term of (12) under this case can be expressed as:

$$\begin{aligned} &\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\}\\ &\geq \Big(\sum_b \overline{\mu}_{ib}^{(c)}\Big)(1 - 2N\alpha\gamma^d) - \Big(\sum_a \overline{\mu}_{ai}^{(c)}\Big)(1 + 2N\alpha\gamma^d)\\ &= \Big(\frac{r_3 - r_2}{N-2}\Big) - \Big(\frac{r_3 + r_2}{N-2}\Big)2N\alpha\gamma^d\\ &\geq \frac{R_1(p-q)\rho\beta}{\theta N}\Big[\delta - \frac{\delta}{N}\Big] \geq \frac{R_1(p-q)\rho(\beta-1)}{4N\theta} \end{aligned}$$

where we used the inequality $2N\alpha\gamma^d < \frac{\delta}{N}$. Combining these two cases, with $\delta = \frac{\beta-1}{2\beta}$ and $\alpha\gamma^d = \frac{(p-q)\rho(\beta-1)}{4\beta(p+q)N^2}$ we have $\mathbb{E}\left\{\sum_b \mu_{ib}^{(c)}(t) - \sum_a \mu_{ai}^{(c)}(t) - A_i^{(c)}(t)|\vec{U}(t-d)\right\} \geq \frac{R_1(p-q)\rho(\beta-1)}{4N\theta}$. Using this in (12), we get:

$$\begin{aligned} \Delta(t,d) \leq &BN(2d+1)\\ &- \frac{R_1(p-q)\rho(\beta-1)}{4N\theta}\sum_{i=1}^{N}\sum_{c\neq i} U_i^{(c)}(t-d) \end{aligned}$$

This is in a form that fits (6). Using the Lyapunov Drift Lemma, we get

$$\limsup_{t\to\infty}\frac{1}{t}\sum_{\tau=0}^{t-1}\sum_{i\neq c}\mathbb{E}\left\{U_i^{(c)}(\tau)\right\}\leq\frac{4BN^2\theta(2d+1)}{R_1(p-q)\rho(\beta-1)}$$

The total input rate into the network is $N\lambda$. Thus, using Little's Theorem, the average delay per packet is bounded by $\frac{4BN\theta(2d+1)}{\lambda R_1(p-q)\rho(\beta-1)}$.
